PRIVACY TECHNOLOGY OPTIONS FOR PROTECTING AND PROCESSING UTILITY READINGS

George Danezis
Paris, Friday, 1 March 2013

SCOPE OF THE DOCUMENT

This document discusses the privacy concerns surrounding the collections and processing of granular readings from next generation utility architectures, such as smart electricity grids. New generation distribution systems rely partially on computerised meters installed in households and businesses that record more information than previous electromechanical meters, and have facilities to transmit them regularly to the energy operators and distributors. A modern smart meter is capable of recording consumption of electricity, as well as production, at a very fine granularity, close to "real time." Most deployments in the US[27] and Europe[28] are presently working toward readings every 15 minutes to 30 minutes respectively (48 or 96 readings per day) uploaded as a single "load profile" about once a day. These are collated with other readings from the same household to build larger load profiles over months or years. This document is concerned with the management and privacy of those detailed readings – other information such as billing details, demographics and subscriber information are broadly similar to information already gathered and benefit from established processes to ensure their security and privacy.

The management of the electricity grid is special, compared to water and gas, in that production and consumption has to be balanced very carefully at all times. Some production requires significant planning to start or stop, and the use of renewables adds uncertainty as to the capacity. These make forecasting and demand response mechanisms important. On the other hand, gas and water provision is also undergoing computerization in its control and distribution, since better recording of consumption could be used to optimize the delivery of those services (like detect leaks). Those attempting to manage privacy issues in smart grids, and the regulatory and technical solutions applied, should therefore foresee that they will create a precedent for the management of other utility data. Furthermore those undertaking privacy impact assessments for managing and processing utility readings should be mindful that combined readings from all utilities may be available at some point, providing a multi-dimensional view into household habits.

Readings and load profiles have direct and indirect uses. They are used directly by the energy industry to monitor and balance production / consumption, forecasting energy needs in the short and long term data, plan for future distribution capacity, and bill customers at a coarse or fine granularity. Where the energy sector is private and competitive, meter readings are also used to settle contracts in the energy market. Billing customers according to the time they consume electricity is particularly promising to provide incentives to reduce consumption at peak time, and is generally called time-of-use tariffs.

Indirect uses are also foreseen for detailed readings for both research and operations: they can be used for monitoring and providing advice on energy efficiency of homes and devices, understand penetration of smart vehicles in different areas, insurance, marketing of renewables, risk management of credit, etc. These are indirect uses since they are not vital for the day to day operation of electricity provision, and may not be performed by the traditional players in the energy industry. In fact, indirect uses are of great interest since they may create new services, or optimize and economically "disrupt" existing ones. Research is a particularly important area that requires data, and by its very exploratory nature, it might require more access than an operational system.

The focus of this document is to provide an overview of technical and other options that support processing of the meter readings to support both direct and indirect uses, and their benefits, while minimizing the exposure of the readings and providing protection of the privacy of households, businesses and government agencies making use of modern grid technologies.

OVERVIEW OF THREATS

Fine grained meter readings recorded by smart meters from households are widely recognized as privacy sensitive. NIST[29], in the US, recommends they are processed as PII (Private Identifiable Information) and jurisdictions with horizontal data protection regimes (Canada and the EU) consider that load profiles fall under their provisions[30]. Substantively, detailed smart meter reading provide a record of activity from within a household that might otherwise be difficult to infer. This activity might be sensitive for occupants. We outline here a number of possible privacy and security threats resulting from the collection and mining of readings:

- Meter readings at the granularity of 15-30 minutes can be used to infer the occupancy of a home, since aggregate half-hourly consumption goes when one is at

home. They leak information about when occupants may be away on holiday, at work or not. As a result compromised readings contain information that could be used to target homes for burglary when they are empty. Interestingly, one of the earliest cases of widespread indirect use of meter readings involved inferring occupancy to detect safe houses of German terrorists[31]. This particular practice was later deemed unconstitutional by German courts.

- Similarly, granular readings can be used to estimate the number of inhabitants at a particular time. Third parties also profile inhabitants in relation to their family situation: for example to discover whether a spouse is working or not. Houses shared by multiple unrelated occupants also exhibit a different pattern of electricity consumption than houses inhabited by a single family.

- Detailed smart meter readings contain information about the sleeping patterns of inhabitants, which can be surprisingly intrusive. Sleeping patterns are associated with specific religious groups: comparatively early morning activity in the months of Ramadan is a sign of a practicing Muslim household. Erratic patterns of sleeping are also indicative of poor health: irregular use of electricity at night may be indicative of early stages of prostate cancer. A change in the use of electricity (for frequent washes) as well as night time patterns of use may indicate to a third party a household with a young child.

- Non-intrusive appliance monitoring[32] techniques detect which appliances are in a home, and when they are used, from fine grained readings of a whole household. While the frequency of readings in current smart-metering deployments is too coarse for a direct application of those techniques, it is clear that some information on appliances, such as the presence of an electric vehicle, a fridge, air-conditioning, or an electric oven can be inferred. It is noteworthy that modern smart meters can be configured, even remotely and without the knowledge of the household, to take readings at a finer granularity. More recent studies have demonstrated under laboratory conditions that electricity consumption can even leak information about which TV channel is being watched[33].

- Even more intrusive information can be inferred when combining electricity with other utility readings, for example water and gas readings. Such combined readings can be used to detect different patterns of cooking in a household, since cooking activity exhibits correlated uses of electricity, gas and water. Similarly, the frequency of use of a dishwasher or washing machine can be inferred. Finally, the combined use of large volumes of water along with either gas or electricity can be

used to infer how often members of the household have showers. Electricity and water provides information about night time patterns of sanitation, and even how often and when inhabitants use the toilet overnight.

Besides the above sample privacy threats, the rationale for storing and processing of meter readings is the extraction of some level of information about a consumer. As such any argument about the value of meter readings at the granularity of a household becomes an argument about potential privacy invasion, as the information originates from, and characterizes, a household. In line with fair information practices[34] this information should only be used with the knowledge and consent of the household, to ensure their best interests are at the heart of any indirect processing.

Besides legal or substantive privacy concerns, smart meter deployments have been jeopardised partly through the poor handling of customer privacy and protection concerns. For example, the smart meter deployment in the Netherlands[35] had to be put on hold due to consumer revolt.

As a result of the above we consider there are serious risks associated with the bulk storage, processing and availability of detailed utility meter readings. First of all, organizations holding such data can be compromised, or lose the data due to mishandling. This is a serious threat to consumers, and the reputation of the entity that that is a victim of a cyber-attack or a mistake. Organizations holding data may also be compelled to reveal the readings they hold, though the legal process of countries they operate in. In some jurisdictions even divorce or private dispute cases can lead to organizations being compelled to reveal information about their customers. Finally, organizations themselves may be tempted to process the readings to gain an unfair advantage in their commercial dealings with customers.

PARTIAL SOLUTIONS AND CAVEATS

A number of solutions are popular to mitigate the perceived risks of handling and processing detailed meter readings. In particular opt-in/opt-out mechanisms, anonymization, and naïve aggregation rules are popular due to their conceptual ease, and relative low cost of implementation. Despite being valuable parts of a larger strategy, in themselves, these mechanisms cannot guarantee the level of protection one would hope for the privacy of readings and households.

Opt-in/Opt-out

Both guidelines for processing PII in the US (fair information processing practices) and data protection regimes consider that, where possible, the informed consent of the data subjects should be sought for any otherwise non-necessary processing. The UK regulator DECC[36] has proposed a gradual system of consent to enable processing of increasingly invasive data: the provision of one reading a month per household is absolutely necessary and therefore obligatory; the provision of a reading per day is subject to customer opt-out, but in its absence collection and processing can go ahead; finally any finer grained processing (as for computing time-of-use tariffs) requires an explicit opt-in from the customer.

The requirement to obtain consent for collection and processing is in itself positive, particularly for indirect uses of readings, where a customer may not have reasonably foreseen it. Yet, it does not alleviate all risks: despite consent to collect and process, readings are still sensitive, and could still be lost or compromised. Therefore some technical protection is still necessary to ensure this sensitive information is stored and processed to minimize its exposure to external or internal risks. Furthermore once bulk readings are available in clear it is difficult to audit what they are used for, to ensure that only authorised processing is taking place.

Finally, a key limitation of solely relying on opt-in as a privacy protection is purely economic. In case time-of-use tariffs become the norm, and added value services relying on energy readings are commonplace, households opting out will find themselves marginalized or possibly unable to benefit from the best prices for the goods and services they receive. Therefore they will be faced with a harsh choice of either opting into a system with poor privacy or being charged a premium for opting out. For this reason it is important to consider additional technical privacy protections even for customers opting in advanced services.

Anonymization

One option for minimizing the danger to households, from the processing of any private information is to first anonymize it. Anonymization[37] removes any personal identifiers from the data in an attempt to make it difficult to link it back to a specific individual or household. Anonymization is an extremely flexible mechanism: full load profiles over time are available to researchers and any function can be computed on them. Sadly, robust

anonymization of load profiles is extremely difficult due to this abundance of data on one side, and the abundance of side information on the other.

Firstly, household energy consumption is rather regular over time. This means that the availability of a short period of non anonymized data can be used to link anonymized load profiles back to the household[38]. Concretely this means that an entity that has a short period of readings from a household, for example a month, can use those readings to pick a longer anonymized load profile related to the same household. To do this, a number of markers would have to be extracted from the raw identified load profile, such as the presence of certain household devices, number of occupants, typical patterns of occupancy related to the schedule of inhabitant's work, school or recurrent appointments. Then the anonymized profiles can be sieved according to the same markers, looking for a match. Different households may be susceptible to this matching to different degrees but some, with very stable unique markers, will be trivially re-identifiable.

Secondly, detailed load profiles are correlated with activities in the home that may be known, public or discoverable by others. Thus markers can be constructed to match other activities linked with specific individuals with anonymized load profiles. Any side-information associated with occupancy can be used[39]: public traffic schedules, a short period of direct physical observation of the home, mobile phone location records or internet access records can be used to construct markers. Thus anyone in the possession of such data sets can create an approximation of a load profile over time, and then attempt to match it with the database of anonymized load profiles. This technique is likely to be much more successful than the previous one, since it does not rely on regularity of habits over time.

For the sake of clarity we present a concrete de-anonymization attack using side-information:

- Consider an on-line web service, like webmail, on which a known target user has an account and checks periodically both from home and outside the home.
- The service logs contain a time series of accesses, and the network address (IP address) of these accesses. The network address leaks whether the user is at home or outside the home, through differentiating between a home internet service provider and a mobile or business internet service provider. Using a different computer at home than at work, can also be leveraged to mount the re-identification attack.

- The service is then provided with a large number of anonymized electricity load profiles, and wishes to re-identify a target user. To achieve this, the service makes the reasonable assumption that a user at home consumes more electricity than a user outside the home.
- For each anonymized trace the services computes this simple statistic: it adds the readings corresponding to times the target user was observed at home, and subtracts the readings when the target user was observed outside the home.
- The anonymous trace corresponding to the target user should achieve a high value of this statistic – ultimately the highest value.

This is the result of the actual trace matching perfectly the observations of occupancy, while other traces being partially independent of it. The more side-information the service has about the user, meaning more accesses to the on-line service, the better the estimation of the statistic and the more confident it can be the de-anonymization attack will be successful. This example illustrates that mounting a de-anonymization attack against an anonymized load profile is computationally cheap, and the side information required only needs to be vaguely related to occupancy – and as such is plentiful and in the hands of many third parties.

De-anonymization techniques may be new in the field of smart-grids, but general techniques are already very mature in related fields of statistical databases privacy or social network privacy. Recently, researchers have demonstrated the inherent dangers of publishing rich anonymized datasets: they managed to de-anonymize a number of users from a dataset of movie preferences published by the Netflix Company using side information from other public sources[40]. In that work they used particular combinations of movie preferences attached to known persons as "markers", and then detected those markers in the anonymized data set to link it to individuals.

Thus, anonymization through the mere removal of obvious identifiers is now recognized as a very weak privacy protection mechanism[41]. It could be used to protect load profiles from mistakes or accidental disclosure, but it is fundamentally a mechanism to keep honest people honest. It cannot protect against a malicious entity that, for example compromised the dataset and is trying to identify specific households.

NAÏVE AGGREGATION RULES

In terms of flexibility another option, besides anonymization, involves providing an "aggregation service" that computes aggregate statistics on specific data items on request,

---

[41] Ohm, Paul. "Broken promises of privacy: Responding to the surprising failure of anonymization." UCLA Law Review 57 (2010): 1701.

and returns only the aggregate results. The hope is that aggregation obscures information about individual households, alleviating privacy concerns. Rules are put in place to ensure each datum is computed on the basis of many households and rounding or suppression can be used to obscure items that do not conform to the rule. One such example is the so-called "15/15 Guideline" that stipulates that at least 15 households are involved in any aggregate.[42]

Sadly there is an extremely mature[43] and rich[44] literature outlining generic attacks against systems that provide the facility to query datasets and return statistics in a naïve manner, despite complex sanitization rules. It has been shown that special queries (called "Trackers") can be crafted, each conforming to the rules, but jointly leaking private information.

Building a tracker for the 15/15 rule is simple. The rule stipulates that a query can only be performed if it concerns a certain minimum number of households: an analyst can submit a query that concerns a large number of specific households (say 1000); then a second query over the same households plus an additional one (namely 1001 records) is performed. The result of the two queries jointly leaks all information about the record that was included in the second query, despite the fact that the queries are compliant with the 15/15 rule. Furthermore, one can show that it is very expensive to audit for sets of queries that are crafted to leak information about single records: one would have to consider the potential leakage of all subsets of queries – and the number of these subsets is very large indeed.

Thus, while allowing querying of a database of records provides flexibility, it has to be supported with great care to ensure no information about individual households is leaked. Positive guarantees of security and privacy must be proven for any sanitization rule to ensure that tracking queries cannot be crafted to extract information.

ROBUST PRIVACY TECHNOLOGY OPTIONS

Privacy protection through procedures or technology is an exercise in risk management that has to balance the benefit of processing the data and the potential privacy risk to households. It is important to note that the benefits of indirect processing may in fact not directly benefit households. Therefore regulators must be very cautious to ensure those benefiting from the processing do not choose alone what constitutes an acceptable risk. In many cases, technology can help to minimize risks, while also maximizing benefits, and thus privacy does not have to be a zero-sum game. A privacy-by-design methodology can

be applied to identify the privacy issues throughout the development of a smart-metering system[45], and appropriate privacy technologies can be deployed to support privacy policies[46].

Sampling Load Profiles, anonymizing & licencing

The first, mostly procedural, option for processing detailed readings is to establish a scheme to provide sampled anonymized load profiles to clearly identified, authorized and overseen researchers for pre-determined uses. In that case anonymization is used to ensure that data leaks do not happen accidentally. A high sampling rate, of say one household in 100-1000 could be used to ensure that any compromise would not leak a very large volume of information, and that any specific target household for which there might be a lot of information is not likely to be in the set of load profiles available for analysis.

Yet, providing anonymized data under a licence or an NDA is not a perfect protection, and some household may have valid reasons to object to taking this risk. It is worthwhile considering explicit opt-in from households for use of load profiles in indirect processing for research through such a scheme. To be fully honest consent should be obtained under the assumption the sharing of the data is not fully anonymized, and possibly financial incentives should be provided to participating households.

On the technical side, getting data under licence should be accompanied with a robust audit of an organizational operations and technical procedures to ensure the security of that data. This should include secure authentication, storage, transport, audit, deletion mechanisms and an ownership structure that ensures the data will be processed according to the licence.

This mechanism is ideally suited for advanced R&D that requires access to full load profiles for exploration. It might also be used to perform computations as part of operations, when complex calculations need to be performed on full load profiles.

Aggregation & Query privacy

The workhorse of most processing is likely to be access to aggregates and statistics based on a number of load profiles. For example, it is legitimate to monitor the aggregate consumption per region, changes over time, or even extract "average" load profiles for researching tariff structures or to train forecasting models. All those uses require readings only as a means to aggregating them into statistics, and not to make decisions on individual

[46] "Smart Meters in Europe: Privacy by Design at its Best." Ann Cavoukian, Ph.D. Information and Privacy Commissioner, Ontario, Canada. April 2012.

households. A number of privacy technologies allow access to those aggregates without making available detailed readings.

To compare to the naïve aggregation rule architectures, architectures that allow secure privacy friendly aggregation rely on a centralized party (or parties) holding the readings, and accepting queries to be performed on the data. Once the query is performed the answer is returned, possibly with some slight modification to ensure that information is not leaked. Queries can be pre-registered and data streams for each query can be produced ahead of time and made available to third parties in real-time.

For simple aggregation, involving sums and weighted sums, a very high degree of privacy can be provided through the use of appropriate encryption technologies[47] [48]. Meter readings can be stored encrypted, thus preventing even the storage service from accessing them in detail. Queries are performed on the encrypted readings, for example to compute encrypted sums over time or space, and returned to the relying services. Special encryption *techniques* can be used that "unlock" the results of queries to uncover the results, without giving access to any individual readings, with the help of a set of authorities overseeing the privacy policy. This architecture ensures that only the final aggregate result is available to anyone processing the readings. No one has access to raw readings, neither the storage service, nor the authorities nor the party receiving the result. Queries can be overseen by authorities for compliance to any policy, or to ensure they are appropriately rate limited to avoid exposing too much information to the any single entity.

Some aggregation is more complex than simple weighted sums. For example non-linear operations might have to be performed on readings before they are aggregated. In those cases the storage service needs to keep the readings in clear and process them to get the results. As we discussed, it is important to ensure no information can leak from specific or repeated tracker queries. One principled framework for achieving this is to ensure that statistics computed are differentially private[49], namely they are not overly influenced by the existence or absence of any single record, irrespective of the others (to protect against side information attacks).

We describe here two example mechanisms for ensuring an arbitrary statistic is differentially private:

---

[47] Klaus Kursawe, George Danezis, Markulf Kohlweiss: "Privacy-Friendly Aggregation for the Smart-Grid." PETS 2011: 175-191

[48] Marek Jawurek, Florian Kerschbaum: Fault-Tolerant Privacy-Preserving Statistics. Privacy Enhancing Technologies 2012:221-238

[49] Cynthia Dwork: A firm foundation for private data analysis. Commun. ACM 54(1): 86-95 (2011)

- The first differentially private mechanism is called "the *Laplacian* mechanism"[50]. One first computes the sensitivity of the statistic, as the maximum difference the inclusion or exclusion of any single item could make to the result of a query. Then some random noise is added to the result, drawn from a specific noise distribution, to mask any specific item, while providing information about the aggregate.
- The second mechanism is called "the *Subsample and Aggregate* mechanism"[51]. It is based on splitting a data set into smaller sub-sets; computing the statistic on each set; and then aggregating the result with some noise. Despite the fact the results are noisy, the average magnitude of the noise added is constant, therefore not overly influencing or biasing the result of queries on larger datasets.

The architecture of submitting queries to a service and getting back results, instead of processing load profiles locally, might be a departure from the habits of some researchers. In case few load profiles are processed a scheme based on licencing a sample of them may be preferable. Yet, in case large volumes of readings have to be processed, centralized *processing in* a data centre or private cloud may be the best option irrespective of privacy concerns. In that case the privacy-friendly architecture, that requires submitting queries to a service, aligns perfectly with the remote processing that would have to take place anyways, and is easy to add to existing computational models such as map-reduce[52]. Query based privacy mechanisms are highly scalable, and provide the ability to audit activity, and very flexible processing. There is no impediment to registering queries ahead of time, and receiving results in real time.

Privacy-friendly query systems can be made very privacy friendly. For simple statistics, they ensure that no single entity can ever get access to raw readings while providing real time access to aggregates and statistics. More complex computations require a storage service to store and process data in clear, but differential privacy mechanism ensure that the results cannot be used to infer much about any single household. They are also very efficient and scale to very large datasets.

USER AUTHORIZATION & DATA EXPORT

Ultimately some who would make indirect uses of meter readings may prefer per-household detailed load profiles. In those cases none of the previous privacy technologies are applicable, since they rely on sampling or aggregation. In such cases the reading storage service can still incentivise a privacy friendly use of the data by third parties by managing user authorization of processing.

---

[52] Dean, Jeffrey, and Sanjay Ghemawat. "MapReduce: simplified data processing on large clusters." Communications of the ACM 51.1 (2008): 107-113.

Conceptually, the storage service can manage the authentication of households to whom the data belongs, as well as services that wish to use the data. The storage service then ensures that permissions to access customer information have been granted by customers for each service. This is not dissimilar to the permission model used by modern mobile platforms (such as *Android* or *Windows Phone*) when an application wishes to access personal data from users. Social network platforms such as *Flickr* or *Facebook*, implement a similar authorization service for third party applications to access user feeds. Google dashboard also provides a model of an interface where a customer can go to manage their authorizations to applications, view and delete the results of computations. Providing such authorization and transparency mechanisms in one central place is highly advised.

Besides providing a well-defined API that allows third party services to access the data, after proper authorization and authentication from customers, the reading storage service can also provide to authenticated users their own household readings to use as they wish. In fact, one of the gravest challenges to privacy – in its information self-determination sense – is that a plethora of services may have access to customer information, when the customer does not. Besides providing access to raw readings, special cryptographic techniques can be used to ensure customer applications can process the data and compute results that can be used with third party services in a privacy friendly manner -- even without leaking the raw readings[53]. These facilities can be used, for example, to produce verifiable time-of-use bills on customer devices, without leaking the raw readings. Any central store of information has a key role to play when it comes to facilitating and enabling a privacy friendly eco-system of applications. If it does not support core privacy services like private aggregation and queries, rich interfaces for authentication, authorization and data export it might block valuable applications due to privacy concerns, or force privacy invasive practices as the only option.

DESIGN FOR PRIVACY

The generic privacy protections presented are quite flexible, but specific applications using electricity readings may have features that make them amenable to other mechanisms for protecting privacy. It is therefore important to include in any R&D program a component that looks at the most privacy friendly way to gain value out of data, and provide rich services.

Unlimited and full access to vast amounts of data and all load profiles in R&D is detrimental to the development of privacy friendly solutions in the long term. The assumption of unlimited availability of data leads to lazy design, where such access becomes a necessity.

---

[53] Rial, Alfredo, and George Danezis. "Privacy-preserving smart metering." Proceedings of the 10th annual ACM workshop on Privacy in the electronic society. ACM, 2011.

Limiting access of researchers to only small sample rich datasets for exploration, and then services for privacy friendly processing of bulk data, incentivises the design of both privacy friendly research methods but also privacy friendly final products, business models, and long term operations.

We have seen that for small focused exploratory research projects, mechanisms based on anonymization, sampling load profiles and opt-in can be used to provide researchers with high quality datasets. For the provision of statistics, privacy friendly query services can provide aggregates or results of arbitrary computations on very large datasets without leaking information about any household. Finally, a proper framework for authorization, authentication and data access by users can enable an ecosystem of privacy friendly third party applications. These facilitate competition, can enable privacy friendly alternatives, and allow the user to have control over who is processing their data as they do in other on-line services.

SHORT BIO

George Danezis is a researcher at Microsoft Research on the topic of computer security and privacy. Before joining Microsoft in 2007 he was a visiting scholar at KU Leuven and a research associate at the University of Cambridge where he completed this PhD in 2004. George Danezis has been the program chair of the Privacy Enhancing Technologies Symposium (PETS) in 2005 and 2006, the conference on Financial Cryptography and Data Security in 2011, and the ACM conference on computer and communications security (CCS) in 2011 and 2012. He has published over 50 peer-reviewed scientific articles on the topics of privacy and security in international conferences and journals, and serves on the board of ACM CCS, PETS and ACM Information Hiding and Multimedia Security.
